Supporting Information

ABSTRACT: This study characterized electrophilic and radical products derived from the metabolism of capsaicin by cytochrome P450 and peroxidase enzymes. Multiple glutathione and β -mercaptoethanol conjugates (a.k.a., adducts), derived from the trapping of quinone methide and quinone intermediates of capsaicin, its analogue nonivamide, and O-demethylated and aromatic hydroxylated metabolites thereof, were produced by human liver microsomes and individual recombinant human P450 enzymes. Conjugates derived from concomitant dehydrogenation of the alkyl terminus of capsaicin were also characterized. Modifications to the 4-OH substituent of the vanilloid ring of capsaicinoids largely prevented the formation of electrophilic intermediates, consistent with the proposed structures and mechanisms of formation for the various conjugates. 5,5'-Dicapsaicin, presumably arising from the bimolecular coupling of free radical intermediates was also characterized. Finally, the analysis of hepatic glutathione conjugates and urinary *N*-acetylcysteine conjugates from mice dosed with capsaicin confirmed the formation of glutathione conjugates of O-demethylated quinone methide and 5-OH-capsaicin *in vivo*. These data demonstrated that capsaicin and structurally similar analogues are converted to reactive intermediates by certain P450 enzymes, which may partially explain conflicting reports related to the cytotoxic, pro-carcinogenic, and chemoprotective effects of capsaicinoids in different cells and/or organ systems.

INTRODUCTION

Capsaicinoids are the pungent compounds in hot peppers. Capsaicin (*trans*-8-methyl-*N*-vanillyl-6-nonenamide) represents ~60–70% of all capsaicinoids in natural sources.¹ Humans are exposed to capsaicinoids through the consumption of peppers, and capsaicinoids (including *cis*- and *trans*-isomers of capsaicin) are also used in an array of consumer products, including topical (e.g., Capzasin-HP and Qutenza/NGX-4010) and injectable (Adlea/ALGRX-4975) analgesics; nasal aerosols to treat allergic rhinitis² and cluster headaches (Civamide; Winston Laboratories);^{3,4} oral supplements for weight loss;⁵ and self-defense pepper spray products.¹ More recently, capsaicinoids have also been investigated as chemopreventive agents.^{6–12}

Pharmacokinetic studies in rodents and humans show that topical and oral administration of capsaicinoids produce high local concentrations and moderate circulating concentrations, depending upon the dose and route of delivery. Using the NGX-4010 skin patch, a 1–1.5 h topical treatment of capsaicin

at ~10 mg/kg in humans produced peak plasma concentrations of ~0.5–18 ng/mL (1.6–58 nM) in the roughly 3–30% of patients where quantifiable capsaicin levels occurred.¹³ Capsaicin was cleared in most patients within 4.5 h, and the estimated $T_{1/2}$ was 1.6 h with AUC values of ~4.4 and 7.7 ng·h/mL (at ~1.5 h) and C_{max} values of 1.4 and 2.9 ng/mL for 1 and 1.5 h patch applications. While detection of P450 metabolites of capsaicin were not reported, substantially higher concentrations of capsaicin and the detection of hydrolysis products and P450 metabolites arising from ω - and ω -1 hydroxylation and terminal dehydrogenation were reported at sites of patch application in a similar study.¹⁴ Orally administered capsaicinoids are also efficiently (85–95% total dose) absorbed from the gastrointestinal lumen, with minor metabolism occurring in the intestine (mainly hydrolysis) but near complete decomposition in the liver.^{15–17} In one study, a

Received: August 28, 2012

5 g oral dose of capsicum (~26.6 mg of capsaicin or ~0.4 mg/kg) in humans yielded peak plasma concentrations of capsaicin of 2.5 ng/mL (~8.2 nM), with T_{\max} , $T_{1/2}$, and AUC values of ~0.78 h, 0.42 h, and ~1.7 ng·h/mL, respectively.¹⁸ It was suggested that the relatively low C_{\max} , short $T_{1/2}$, and low AUC were the result of extensive metabolic decomposition, consistent with prior studies.^{15,16} In a second study, oral dosing of rats (30 mg/kg; ~5× average daily intake of capsaicinoids by individuals in India but where “beneficial effects have been observed”) demonstrated 94% absorption from the intestine with a peak serum concentration of 6.2 μ M.¹⁹ In this same study, substantially higher amounts were found in the liver (~45 mg/tissue), kidney (~7 mg/tissue), and intestine (~1,060 mg/tissue). However, the formation of P450-derived metabolites was not evaluated in either of these studies. Given reports that the average capsaicin intake for humans is 0.5–4 mg/kg/day (EC Scientific Committee on Food, 2002, http://ec.europa.eu/food/fs/sc/scf/out120_en.pdf) and that commonly used products containing capsaicinoids can produce substantial local and circulating levels of capsaicinoids, there is a critical need to understand how capsaicinoids interact with drug metabolizing enzymes, including the formation of reactive intermediates that may have extensive effects on biological systems.

Prior studies of the metabolism of capsaicinoids by P450 enzymes characterized a macrocycle metabolite where the ω -1 carbon became covalently bound to the amide nitrogen (M1), ω - and ω -1 alcohols (M2 and M3), an alkyl terminal diene (M4), two aromatic hydroxylated products (M5 and M7), an O-demethylated catechol (M6), a unique oxygenated imide (M8), and an imide (M9)^{20,21} (see Figure 7 for structures). Additionally, three glutathione (GSH) conjugates presumably derived from O-demethylation (M6), aromatic hydroxylation (M5 and M7), and the oxygenated imide (M8) were observed,²⁰ but the origins and characteristics of these GSH-conjugated metabolites were not thoroughly investigated.

The current study characterized the biochemical pathways leading to the formation of reactive intermediates from capsaicinoids by P450 enzymes, in an effort to better understand the relationship between P450-dependent metabolism and the effects of capsaicinoids on humans and animals. These studies also provide new insights into the likely metabolic fate of structurally related chemicals including olvanil, arvanil, linvanil, eugenol, capsates, and gingerols.

MATERIALS AND METHODS

Chemicals. Capsaicin (97%), nonivamide (*N*-vanillylnonanamide), NADPH, reduced glutathione (GSH), β -mercaptoethanol (BME), silver oxide, horseradish peroxidase (HRP; EC 1.11.1.7), hydrogen peroxide, H_2^{18}O , octanoyl chloride, nonanoyl chloride, and CDCl_3 were purchased from Sigma-Aldrich (St. Louis, MO). 2-Chloronicotinoyl chloride was purchased from Alfa Aesar (Ward Hill, MA). HRP concentration was determined spectrophotometrically using the extinction coefficient $\epsilon_{402} = 1.02 \times 10^5 \text{ M}^{-1} \text{ cm}^{-1}$ and H_2O_2 using the extinction coefficient $\epsilon_{240} = 39.4 \text{ M}^{-1} \text{ cm}^{-1}$. *N*-Benzylnonanamide, *N*-(3-hydroxy-4-methoxybenzyl)nonanamide, *N*-(3,4-dihydroxybenzyl)nonanamide, *N*-(3-methoxybenzyl)nonanamide, *N*-(3,4-dimethoxybenzyl)nonanamide, and *N*-(4-hydroxybenzyl)nonanamide were synthesized as previously described.²²

Metabolic Incubations. Pooled human liver microsomes and individual recombinant P450 enzymes were purchased from BD Biosciences (Franklin Lakes, NJ). Incubations (250 μ L) in phosphate-buffered saline, pH 7.2, contained ~50 pmol P450 (human liver microsomes) or 25 pmol recombinant P450 enzyme, 2.5 mM NADPH, 2.5 mM GSH (or 1 mM BME when used in place of

GSH), and capsaicin or capsaicinoid analogue, typically at 25 or 100 μ M. Reactions were performed at 37 °C and P450 turnover was initiated by the addition of NADPH (2.5 mM). Reactions were terminated by adding 150 μ L of methanol containing 0.1 ng/ μ L internal standard; nonivamide was the internal standard for incubations containing capsaicin, and capsaicin was the internal standard for incubations containing nonivamide and the various synthetic analogues. Samples were clarified by centrifugation at 21,000g for 5 min, the supernatant was transferred to a clean tube, dried in a vacuum centrifuge, and stored frozen until assayed by LC/MS, as described below. In separate experiments utilizing HRP (25 nM) as the enzymatic catalyst for reactive intermediate formation, samples were prepared in 50 mM sodium acetate, pH 5.5, at room temperature and initiated by the addition of 500 μ M H_2O_2 . Reactions using HRP were processed as described above. For the determination of K_m and the relative proportions of conjugate formation (Table 1),

^aApparent K_m values were generated from concentration–metabolite abundance curves, as described in the Materials and Methods section. ---, Indicates that the K_m was not calculated. N.D. indicates not detected. The designation “atypical” refers to the fact that formation of conjugate did not exhibit a normal Michaelis–Menten dose–response, that is, maximum rates of formation occurred at lower concentrations, and at higher concentrations, the rates were diminished, presumably due to competition between capsaicin and dehydrogenated capsaicin for the enzyme active site. ^bThe % total value was derived from dividing the area under the concentration-normalized peak area curve for each conjugate by the total AUC for all conjugates. ^c*, refers to the G* (i.e., alkyl dehydrogenated forms) of the GSH conjugates.

samples were prepared using substrate concentrations of 0.5, 1, 2.5, 10, 25, 50, 100, 250, and 500 μ M. A 5 min incubation time was used for P450 studies and 1 min for HRP. Conjugate abundances, relative to the internal standard, were plotted versus the concentration of substrate and fit with the Michaelis–Menten equation. For the determination of relative quantities of conjugates, the concentration–response curve was integrated and the area under the curve for each

Figure 1. LC/MS² chromatograms and spectra for the major GSH conjugates of capsaicin. Reactions were performed as outlined in the Materials and Methods section using human liver microsomes and a concentration of 100 μ M capsaicin. The identities of the conjugates and the specific MS² criteria used for the analysis of each conjugate are provided for each chromatogram. All chromatograms are full scale for the precursor-to-product ion transition listed in the figure.

individual conjugate divided by the total AUC for all conjugates. *Note:* Differences in ionization efficiency could not be accounted for because analytical standards are not available for the GSH conjugates. Thus, data are relative values.

General LC/MS Methods. Sample residues were resuspended in 70 μ L of 70% methanol/30% dH₂O, clarified by centrifugation, and transferred to autosampler vials for analysis. GSH conjugates were assayed by LC/MS² using a Thermo LCQ Advantage MAX (Thermo-Fisher, San Jose, CA) ion trap mass spectrometer interfaced with a Surveyor LC system. Samples (15 μ L) were injected onto an Inertsil ODS-4 150 \times 2.1 mm, 3 μ m C₁₈ reverse-phase HPLC column (GL Sciences, Inc. Tokyo, Japan). The column was equilibrated at 40 °C with a mobile phase comprising 50% methanol and 50% 0.1% (v/v) formic acid at 0.2 mL/min. GSH conjugates were eluted using the following LC gradient: 50% methanol from 0 to 20 min; 50→55% methanol from 20.1 to 23.5 min; 55→95% methanol from 23.6 to 25 min; 95% methanol from 25→30 min; and 50% methanol from 30.1 to 40 min. For BME conjugates, the LC gradient was as follows: 45→60% methanol from 0 to 30 min; 60% methanol from 30→45 min; and 45% methanol from 45→60 min. The mass spectrometer was operated in positive electrospray ionization mode using parameters optimized to detect capsaicin. The sheath gas pressure (N₂) was 50 units, the capillary temperature was 275 °C, and the capillary voltage was 5 kV. A collision offset value of 30% was used for MS², and either selected-ion monitoring as outlined in Table 1 or full-scan product ion spectra were collected.

GSH and BME Conjugate LC/MS Analysis Parameters. Initial studies of GSH conjugate formation utilized data-dependent neutral-loss scanning for analytes that liberated pyroglutamate (−129 amu) or GSH (m/z 308) during MS² analysis, as described by Baillie et al.²³ The m/z values for GSH conjugates produced from capsaicin using human liver microsomes were 595, 597, 609, 611, 625, and 627. Subsequent targeted MS² analysis of GSH conjugates utilized these MH⁺ ions and collection of full scan (m/z 180→650) data for structural characterization, or selected reaction monitoring (SRM), using the ions indicated in the various figures herein. Analysis of GSH conjugates of nonivamide and other capsaicinoid analogues were adjusted to account for differences in the mass of the substrate (e.g.,

−12 amu for nonivamide vs capsaicin). Conjugates of capsaicin with BME were assayed using the following MH⁺ values, based on the results for GSH conjugate formation: m/z 366, 368, 380, 382, 396, and 398. Full-scan MS² data (m/z 100→400) were also collected for conjugate identification.

Interpretation of MSⁿ Spectra. Interpretation of MS² and MS³ spectra obtained for the GSH and BME conjugates of capsaicin, for purposes of structural elucidation, was facilitated by Mass Frontier 4.0 Software (Thermo, San Jose, CA). All software predictions were performed using default parameters.

¹⁸O Incorporation Studies. Differentiation of hydration of quinone methide intermediates versus P450-catalyzed hydroxyl rebound mechanisms for the formation of hydroxylated GSH conjugates was achieved by measuring ¹⁶O versus ¹⁸O incorporation into the conjugates from water. Fractional incorporation of ¹⁸O was calculated using Brauman's least-squares method and 2-chloronicotinoyl chloride as a positive control, as previously described.²⁴ Incubations were performed in 50% v/v H₂¹⁸O.

Synthesis and NMR Analysis of Conjugate B6 (G6). Capsaicin (2 mg) was dissolved in 2 mL of dry acetonitrile and heated to 60 °C. Silver oxide powder (150 mg) was added to the solution, and the reaction was constantly mixed at 60 °C for 7.5 min. The mixture was passed through a paper filter to remove the silver oxide and collected in a tube containing 200 μ L of BME. The solution was mixed, dried under N₂, reconstituted in 200 μ L of 70% methanol/water, and the resulting BME B6-conjugate enriched by HPLC using the conditions described above for capsaicin BME conjugate analysis. [¹H]-NMR of B6 was obtained at 600 MHz on a Varian INOVA equipped with a cryogenically cooled [¹H] channel in 600 μ L of CDCl₃ (99.96% D).

Preparation and NMR Analysis of 5,5'-Dicapsaicin. Capsaicin (500 μ M) was incubated with HRP (500 nM) and H₂O₂ (1 mM) in 250 μ L of 50 mM sodium acetate, pH 5.5, for 10 min at room temperature. Reaction products from a 10 mL reaction were extracted into 10 mL of *n*-butyl chloride two times, the organic extracts pooled, and dried under N₂. The dried residue containing the dimer product was reconstituted in 200 μ L of 70% methanol/water and enriched by HPLC by collecting the peak eluting at ~46.5 min (Figure 6) using the HPLC conditions described above for GSH conjugate analysis. [¹H]

Figure 2. Illustration of the diagnostic precursor-to-product ions and structures of the major GSH conjugates of capsaicin. Additional fragmentation ion data are provided in Supporting Information Figures 7–9. Similar data for the corresponding BME conjugates of capsaicin are also provided in Supporting Information Figures 12–14.

and ^{13}C NMR were obtained at 600 MHz on a Varian INOVA equipped with a cryogenically cooled ^1H channel in 100 μL of CDCl_3 (99.96% D) in a 5 mm Shigemi NMR tube matched to CDCl_3 . ^1H -NMR data are shown in Supporting Information Figure 1. Gradient heteronuclear single quantum coherence (gHSQC) NMR spectra were also acquired to ascertain the structure of the dimer product. Likewise, esterification of the dimer using nonanoyl chloride was used to confirm the dimer structure. This was performed by reacting excess nonanoyl chloride with the enriched dimer product in 100 μL of 0.1 N NaOH (30 min at RT) followed by extraction of the product into *n*-butyl chloride, drying under N_2 , and subsequent MS^2 and MS^3 analysis of the doubly esterified product (Supporting Information Figure 2).

Synthesis of *N*-(Trimethoxybenzyl)nonanamide Analogues.

For elucidation of the sites of aromatic hydroxylation for capsaicinoids (i.e., M5 and M7) and the corresponding GSH conjugates (G7, G8, and G9), *N*-(3,4,5-trimethoxybenzyl)nonanamide, *N*-(2,3,4-trimethoxybenzyl)nonanamide, and *N*-(2,4,5-trimethoxybenzyl)nonanamide were synthesized. 3,4,5-Trimethoxybenzylamine (Sigma), 2,3,4-trimethoxybenzylamine (Matrix Scientific, Columbia, SC), and 2,4,5-trimethoxybenzylamine (Matrix Scientific) were reacted with an equimolar quantity of nonanoyl chloride and purified as previously described for the other nonivamide analogues.²² ^1H -NMR spectra of the products are shown in Supporting Information Figures 3–5.

Analysis of GSH Conjugates in Mouse Liver. TRPV1 $^{-/-}$ mice (~10 weeks; $n = 3$) were treated i.p. with 10.0 mg/kg capsaicin (in 50% ethanol). Mice were sacrificed 30 min after treatment by lethal injection (100 mg/kg pentobarbital), and their livers were excised. The livers were washed, homogenized in ~5 volumes of 50% methanol/water, and centrifuged at 2,500g for 10 min and again at 100,000g for 60 min. The supernatant was then lyophilized. The residue was reconstituted with 50% methanol/water and again clarified by centrifugation at 20,000g for 5 min prior to analysis for GSH conjugates using the following precursor-to-product ion transitions: m/z 597 \rightarrow 468, 611 \rightarrow 308, 611 \rightarrow 482, and 627 \rightarrow 498.

Analysis of *N*-Acetylcysteine Conjugates in Mouse Urine.

Female CD-1 mice were treated p.o. or i.v. with 2.5 mg/kg capsaicin, and urine was collected at 24 ($n = 5$), 48 ($n = 2$), and 96 h ($n = 2$) and pooled for each time point. Urine (1.5 mL) was fortified with internal standard (nonivamide) at 100 ng/mL, diluted 2 \times in phosphate-buffered saline, pH 7.2, clarified by centrifugation, and loaded onto a 3 mL Hypersep C₁₈ solid-phase extraction column (Thermo Scientific, Bellefonte, PA). The columns were washed with dH_2O and the analytes eluted using methanol. The extracts were dried under N_2 and

reconstituted in mobile phase for LC/MS analysis. Conjugates previously identified through *in vitro* P450 incubations using *N*-acetylcysteine as the nucleophilic trapping agent were assayed using a GL Sciences C₁₈ HPLC column (150 \times 2.1 mm) with a mobile phase of 57.5% methanol/42.5% aqueous formic acid at 0.2 mL/min at 40 $^\circ\text{C}$ (Supporting Information Figure 6). The following precursor-to-product ion transitions were monitored using positive electrospray ionization: m/z 453 \rightarrow 284, 467 \rightarrow 298 + 304, 482 \rightarrow 314, 306 \rightarrow 137, and 294 \rightarrow 137 for conjugates of O-demethylated, unmodified, and hydroxylated capsaicin, free capsaicin, and nonivamide.

RESULTS

GSH Conjugates. Representative chromatograms and the corresponding MS^2 spectra of nine GSH conjugates produced from capsaicin by human liver P450 enzymes are shown in Figure 1. The structures of specific diagnostic fragment ions for the various GSH conjugates are shown in Figure 2 and Supporting Information Figures 7–9. Additional characteristics are summarized in Table 1. Data comparing the production of the various GSH conjugates by individual recombinant P450 enzymes are in Figure 3 (25 μM substrate concentration) and Supporting Information Figure 10 (100 μM substrate concentration). Chromatograms and spectra for minor “G*” conjugates (Table 1), derived from the trapping of identical electrophiles of an alkyl dehydrogenated metabolite of capsaicin (i.e., M1 or M4),^{20,21} are shown in Supporting Information Figure 11.

BME Conjugates. In parallel studies, BME was used as the nucleophile to facilitate metabolite identification from MS^2 spectra that were not dominated by fragmentation of GSH, as shown in Figure 1. Chromatograms and spectra of the BME conjugates B1–B9, corresponding to G1–G9, are presented in Supporting Information Figure 1, and the structures of diagnostic fragment ions for B1–9 are shown in Supporting Information Figures 13 and 14.

G1 and G2. MS^2 analysis of the minor G1 conjugate pair (m/z 597 \rightarrow 308 at 14.4/15.9 min) and the major G2 conjugate pair m/z 597 \rightarrow 468 at 17.7 and 19.0 min in Figure 1 indicated the trapping of O-demethylated capsaicin (291 g/mol). The major fragment ion for G1 was m/z 308, representing GSH liberated from the conjugate (Figure 2, Supporting Information

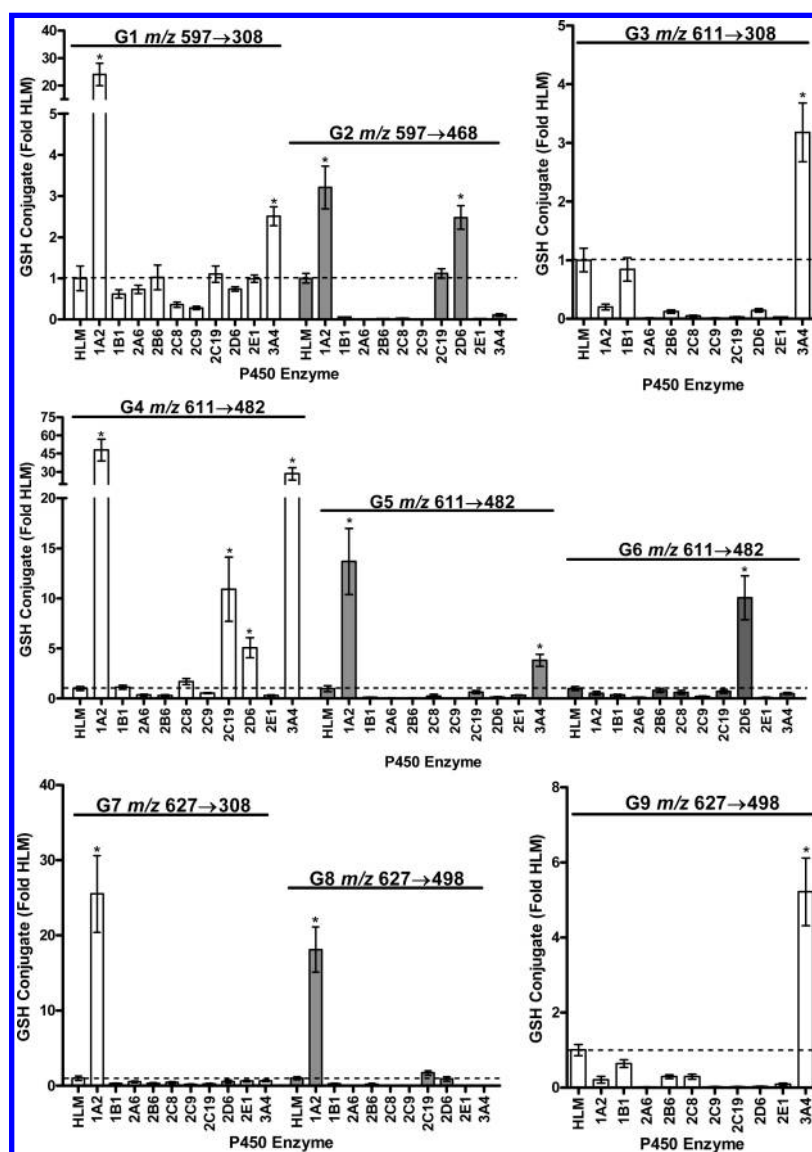

Figure 3. Production of the various GSH conjugates of capsaicin by individual recombinant P450 enzymes. Reactions were performed as outlined in the Materials and Methods section with a concentration of 25 μ M capsaicin. Data using a 100 μ M concentration and additional P450 enzymes are presented as Supporting Information Figure 10. The identities of the conjugates and the specific MS² analysis parameters used for metabolite detection are provided in the figures above the corresponding results from the enzyme screen. All data are relative to the amount of conjugate observed using human liver microsomes ($n = 3$). *Represents a statistical difference in the amount of conjugate produced by a specific P450 enzyme relative to human liver microsomes using ANOVA and $p < 0.05$.

Figure 7, top panel). This fragmentation pattern is characteristic of allylic GSH conjugates,²³ indicating that G1 was diastereomers with GSH attached to the C₇ benzylic carbon of O-demethylated capsaicin (M6). The proposed mechanism of G1 formation is presented in Figure 7.

The diagnostic fragment ions for G2 were m/z 597, m/z 522, and m/z 468 (Figures 1 and 2). These fragmentation properties are characteristic of the loss of glycine (−75 amu) and pyroglutamate (−129) from GSH, and occur when GSH is attached to an aromatic carbon.²³ Thus, G2 formed from the addition of GSH to the aromatic vanilloid ring of O-demethylated capsaicin (M6) at the C₂, C₅, or C₆ carbons (Figure 7). Consistent with the proposed mechanisms of formation and structural assignments in Figure 7, the formation of equivalent conjugates from capsaicinoid analogues lacking the 4-OH vanilloid ring constituent (i.e., *N*-benzylnonanamide, *N*-(3-methoxybenzyl)nonanamide, and *N*-(3,4-

dimethoxybenzyl)nonanamide) was diminished; was unchanged for analogues with either the exact or similar vanilloid ring structure (i.e., nonivamide and *N*-(3-hydroxy-4-methoxybenzyl)nonanamide); or was increased for *N*-(3,4-dihydroxybenzyl)nonanamide and *N*-(4-hydroxybenzyl)nonanamide (Supporting Information Figure 15).

Characteristics of G1 and G2 Production. O-Demethylation of capsaicin was previously shown to be catalyzed by CYP1A2 and 2C19 and to a lesser extent by CYP3A4 and 2D6.²⁰ Here, G1 and G2 were produced by CYP1A2, 2C19, 3A4, and 2D6 (Figure 3 and Supporting Information Figure 10). Trapping of O-demethylated capsaicin that was dehydrogenated on the terminal alkyl position (i.e., G1* and G2*) was also observed (Supporting Information Figure 11). G1* (8.7 min) and G2* (11.1 min) had molecular ions of m/z 595, consistent with trapping of an electrophile with a mass of 290 g/mol. No change in the m/z 308 fragment was observed for

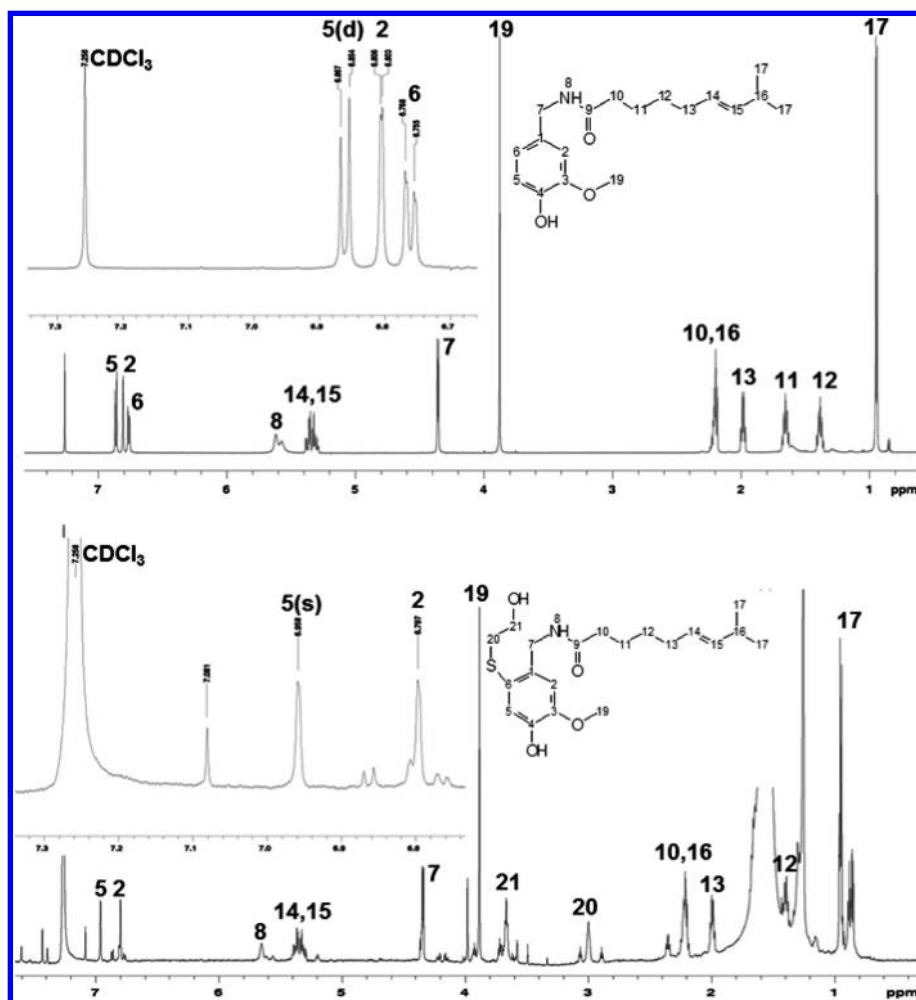

Figure 4. ^1H -NMR spectrum (600 MHz) for capsaicin and B6, the BME equivalent of G6. The top spectrum is for capsaicin, and the bottom spectrum is for B6. Insets provide an expansion of the aromatic proton resonances for capsaicin and B6. Data were collected as outlined in the Materials and Methods section.

G1*, but the presence of m/z 428 for G2* indicated neutral loss of a dehydrogenated alkyl side chain (-167), versus -169 for capsaicin.²⁰ G2 was the most abundant GSH conjugate ($\sim 71\%$ total), and the calculated K_m for the formation was ~ 40 μM (Table 1); G1, G1*, and G2* were all $<1\%$ of the total GSH conjugates.

B1 and B2. B1 (corresponding to G1) and B2 (corresponding to G2) conjugates with an m/z value of 368 were observed at 7.6/10.3 min and 28.1/30.4 min (Supporting Information Figure 12). The m/z 368 ion of the B1 and B2 conjugates was consistent with the addition of BME ($+76$ amu) to O-demethylated capsaicin (m/z 292). B1 uniquely fragmented to m/z 322, which was attributed to the loss of $\text{C}_2\text{H}_6\text{O}$ (-46 amu) from BME attached to the C_7 carbon, with additional loss of H_2O to form m/z 304 (Supporting Information Figure 13, top panel). Additionally, m/z 169 in the spectrum for B1 was consistent with an O-demethylated ring structure with $-\text{SCH}_2$ attached to the C_7 benzylic carbon. The MS^2 spectrum of B1 also lacked diagnostic fragment ions corresponding to the alkyl side chain of capsaicin at m/z 170 and 153.²⁰

B2 fragmented to m/z 199, 196, and 181, consistent with BME attached to the aromatic O-demethylated vanilloid ring minus the alkyl side chain of capsaicin (Supporting Information Figures 12 and 13). Consistent with this structural assignment,

scission of the amide bond also yielded m/z 170, 153, and 135, which corresponded to the unmodified alkyl fragments of capsaicin, as previously reported.²⁰ Using nonivamide as the substrate, the fragment ion pattern for B1 was unchanged, despite a -12 amu shift in the molecular ion m/z 368. However, for B2 of nonivamide, the alkyl fragment ions m/z 170, 153, and 135 observed with capsaicin were appropriately shifted by -12 amu, further confirming the structures shown for B1/G1 and B2/G2 in Figure 7.

Identification of G3/G3* and Characteristics of Formation. The MS^2 spectra of the two major analyte peaks for G3 in Figure 1, m/z 611 \rightarrow 308 at 20.1/21.9 min, were indistinguishable. The MH^+ ion of m/z 611 was consistent with GSH addition to unmodified capsaicin (305 g/mol). Like G1, the spectrum of G3 indicated liberation of GSH (m/z 308). Additional diagnostic fragment ions for G3 included m/z 442 attributable to GSH attached to the unmodified vanilloid ring as a result of neutral loss of 169 amu (i.e., the alkyl side chain of capsaicin) (Figures 1 and 2, Supporting Information Figure 7, bottom panel). From these data, it was concluded that G3 was diastereomers derived from the addition of GSH to the C_7 benzylic carbon of a quinone methide intermediate (Figure 7). Similar to G1 and 2, a minor G3* conjugate arising from either bioactivation of the vanilloid ring of M1 or M4 was observed (Supporting Information Figure 11). G3* liberated m/z 308

Figure 5. Formation of aromatic alcohols M5, M7, and M8, and GSH conjugates G8 and 9 from *N*-(trimethoxybenzyl)nonanamide analogues. (Left) Formation of aromatic alcohols M5 and M7 (m/z 310→153), (center) M8 (m/z 308→168), and (right) G8 and G9 (m/z 615→486) from nonivamide (black), *N*-(2,3,4-trimethoxybenzyl)nonanamide (red), *N*-(2,4,5-trimethoxybenzyl)nonanamide (green), or *N*-(3,4,5-trimethoxybenzyl)nonanamide (blue) in incubations with human liver microsomes plus or minus GSH.

but had an MH^+ ion of m/z 609, consistent with alkyl dehydrogenation of capsaicin prior to vanilloid ring metabolism to an electrophilic quinone methide intermediate. G3 was produced mainly by CYP3A4 and 1B1 (Figure 3 and Supporting Information Figure 10) and was roughly the third most abundant GSH conjugate detected (5%), with a K_m of ~ 40 μM (Table 1). Formation of G3 from nonivamide was comparable to that of capsaicin (Supporting Information Figure 16) but absent for all analogues lacking a 4-OH moiety (i.e., *N*-benzylnonanamide, *N*-(3-hydroxy-4-methoxybenzyl)nonanamide, *N*-(3,4-dihydroxybenzyl)nonanamide, *N*-(3-methoxybenzyl)nonanamide, and *N*-(3,4-dimethoxybenzyl)nonanamide). Conversely, G3 formation from *N*-(4-hydroxybenzyl)nonanamide was greater, consistent with a quinone methide intermediate being the source of G3. The apparent lack of G3 formation from *N*-(3,4-dihydroxybenzyl)nonanamide but extensive formation of G2 and G6 (Supporting Information Figures 15 and 16) suggests that this analogue readily forms a 3,4-quinone intermediate rather than a quinone methide.

Analysis of B3. A BME conjugate pair, B3, corresponding to G3 (m/z 382→213) eluted at 24.5/26.4 min, was observed (Supporting Information Figure 12). B3 fragmented to m/z 213 corresponding to the vanilloid ring + BME (i.e., m/z 137 + 76 amu; Supporting Information Figure 13, middle panel), m/z 195 corresponding to m/z 213- H_2O , and the characteristic alkyl chain ions of capsaicin at m/z 170 and 153,²⁰ consistent with the proposed structural assignment and mechanism of formation for G3 (Figure 7).

Identification of G4–6 and Characteristics of Formation. G4 and G5 (16.8 and 19.5 min; m/z 611→464) and G6 (m/z 611→482; 23.4 min) in Figure 1 were spectrally similar. Unlike G3, the MS² spectra for these relatively minor conjugates were characterized by neutral loss of glycine (m/z 536), pyroglutamate (m/z 482), and pyroglutamate plus H_2O (m/z 464), consistent with GSH being attached to the aromatic vanilloid ring of an intermediate quinone methide (Figure 7). CYP1A2, 3A4, 2C19, and 2D6 produced G4–G6, with 2D6

being the primary catalyst for G6 (Figure 3 and Supporting Information Figure 10). Corresponding G4–G6* conjugates were also observed (Supporting Information Figure 11), and like the other G* conjugates, only the fragment ions containing the dehydrogenated alkyl chain were decreased –2 amu. G4 and G5 formation was minimal for all of the capsaicinoid variants except nonivamide, which was roughly equivalent to capsaicin. However, G6 formation was increased for *N*-(3,4-dihydroxybenzyl)nonanamide (Supporting Information Figure 16), suggesting that the origin of G6/B6 may be an intermediate 3,4-quinone with GSH/BME attached to the aromatic ring at either the C₂, C₅, or C₆ positions.

NMR Analysis of B6 (G6). Because the identity of B6 (G6) was not fully elucidated through MSⁿ analysis, and it was a major conjugate, the structure was pursued using NMR. The [¹H]-NMR spectrum of synthetic B6 (Figure 4) was characterized by a loss of the doublet at 6.76 ppm attributable to the proton on C₆, a shift in the resonance for the C₅ proton from 6.86 to 6.96 ppm, loss of coupling (i.e., conversion to a singlet) between the C₅ and C₆ protons at 6.86 ppm for the proton on C₅, loss of long-range coupling between the C₂ and C₆ protons, and the appearance of two new resonances at ~ 3.0 and 3.65 ppm, attributable to the two methylene carbons of BME. Thus, the identity of B6 (G6) was concluded to be capsaicin with the thiol trapping agent attached to the C₆ carbon, presumably derived from a quinone methide intermediate.

Identification of G7–G9. MS² analysis of the G7 conjugate pair (m/z 627→308 at 14.5/16 min.), the G8 conjugate pair (m/z 627→498 at 19.1/21.5), and the G9 conjugates (m/z 627→498 at 25.6/26.7 min) (Figures 1 and 2) indicated trapping of an electrophile derived from hydroxylated capsaicin (321 g/mol) (i.e., a catechol), presumably M5, M7, or M8.²⁰ The diagnostic fragment ions for G7 were hydroxylated capsaicin plus GSH (m/z 627) and the liberation of GSH (m/z 308) and the unmodified alkyl chain (m/z 458). G7 was characterized by essentially symmetrical peaks, consistent with diastereomers arising from attachment of GSH to the C₇

benzylic carbon of an intermediate quinone methide produced after hydroxylation of the vanilloid ring (Figure 7). Conversely, G8 and G9 exhibited the neutral loss of glycine (-75) and pyroglutamate (-129), to yield m/z 552 and 498, respectively, consistent with GSH addition to the aromatic ring and two different carbon atoms.

Aromatic hydroxylation of capsaicin was previously shown to be catalyzed by CYP1A2 and 2C19 (M5), and 2B6, 2C8, and 2E1 (M7), while M8 production occurred with multiple enzymes including CYP3A4, 1A1, 2E1, 2C8, 2D6, and 2B6.²⁰ G7 and G8 were produced mainly by CYP1A2, suggesting these conjugates were derived from M5. Metabolism of *N*-(3,4,5-trimethoxy)nonanamide by human liver microsomes yielded an aromatic hydroxylated metabolite exhibiting an identical precursor-to-product ion transition (m/z 310 \rightarrow 153; blue chromatograms) and HPLC retention time as nonivamide (black chromatograms), but neither *N*-(2,3,4-trimethoxy)nonanamide (red chromatograms) nor *N*-(2,4,5-trimethoxy)nonanamide (green chromatograms) produced this metabolite (Figure 5, bottom left panel). From these data, it was concluded that M5 of capsaicin and nonivamide was the result of hydroxylation at the C_5 position. Metabolism of *N*-(3,4,5-trimethoxy)nonanamide in the presence of GSH also produced conjugates with LC/MS characteristics identical to G7 (not shown) and G8 (Figure 5, bottom right panel, blue chromatogram), indicating that G7 and G8 are presumably formed by an intermediate quinone methide produced from 5-OH-capsaicin/nonivamide with the addition of GSH at either the C_7 benzylic position to yield diastereomers (G7) or at the C_3 or C_6 positions to yield G8 (Figure 7). Using *N*-(2,3,4-trimethoxy)nonanamide as a substrate, neither M5, M7, M8, G7, G8, nor G9 was observed (Figure 5, red chromatogram, left side). Rather, a peak corresponding to a previously unidentified aromatic hydroxylated metabolite eluting at 15.3 min was observed, consistent with 3-OH-capsaicin/nonivamide. However, none of the GSH conjugates from this substrate corresponded with those of capsaicin or nonivamide. Finally, using *N*-(2,4,5-trimethoxy)nonanamide as a substrate, it was demonstrated that M7 was 6-OH-capsaicin (Figure 6, green chromatogram, left side). Additionally, this substrate uniquely yielded M8 (Figure 5 green chromatogram, center panel), indicating that M8 involved C_6 oxygenation, contrary to the structure previously proposed.²⁰ *N*-(2,4,5-Trimethoxy)nonanamide also uniquely produced G9 (Figure 5, green chromatogram, right side), demonstrating that G9 was formed from M7, presumably via dehydrogenation of M7 at the C_7 -NH bond and tautomerization to an electrophile (Figure 7), based on the relative production of M8 and G9 by CYP3A4 and 1A1, which are the dominant enzymes for catalyzing M8 formation and *N*-dehydrogenation of capsaicinoids.²⁰ Assays using all the other analogues (Supporting Information Figures 17 and 18) were generally uninformative.

Characteristics of G7–G9 Formation. For G7–G9, hydroxylation occurred via direct P450-catalyzed oxygenation since incorporation of ^{18}O from H_2^{18}O was not observed (not shown). G^* conjugates of G7–G9 were also observed (Supporting Information Figure 11). The MH^+ ion for G7^* (9.3 and 10.2 min.), G8^* (11.8 and 13.1 min.), and G9^* (15.4 and 16.2 min) was m/z 595, with no change in the diagnostic fragment ions of G7^* relative to G7 (i.e., m/z 308), and -2 amu shifts in the fragment ions for G8^* and G9^* relative to G8 and G9, consistent with alkyl dehydrogenation. G8 ($\sim 3\%$) and G9 ($\sim 17\%$) were the fourth and second most

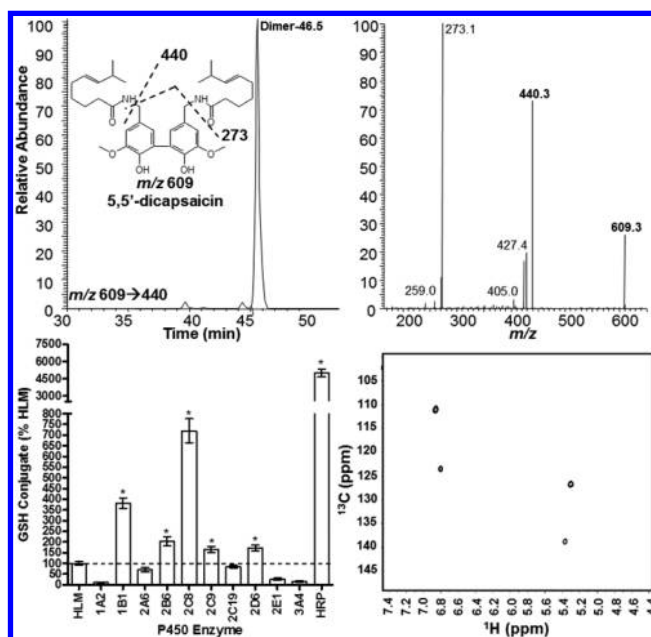

Figure 6. Chromatographic, spectral, and enzyme-specific production of 5,5'-dicapsaicin by human P450 enzymes and horseradish peroxidase. The top panel shows an extracted ion LC/MS² chromatogram and the corresponding MS² spectrum with illustrated fragmentation pathways for 5,5'-dicapsaicin (m/z 609). The bottom left panel shows quantitative results for the formation of 5,5'-dicapsaicin by individual human P450 enzymes and horseradish peroxidase. The bottom right panel shows the gHSQC spectrum used to confirm 5,5'-dicapsaicin. *Represents dimer production in excess of the quantity produced by human liver microsomes using ANOVA and $p < 0.05$. Reactions were prepared as described in the Materials and Methods section.

abundant GSH conjugates produced (Table 1), while G7 was minor. The K_m values for G7, G8, and G9 were 4, 18, and 10 μM , respectively (Table 1).

Analysis of B7–B9. B7 (corresponding to G7), B8 (corresponding to G8), and B9 (corresponding to G9) conjugates were observed with m/z values of 398 at 23.4/25.4 min, 30.2/34.1 min, and 37.5 min (Supporting Information Figure 12). The MH^+ ion of 398 was consistent with the addition of BME (76 amu) to hydroxylated capsaicin (m/z 322; presumably M5). B7 fragmentation to a unique m/z 246 ion was predicted to arise from the addition of BME to the vanilloid ring at the C_7 position (Supporting Information Figure 14, top panel). B7 was also produced by CYP1A2, similar to G7 (not shown). B8 and B9 fragmented to m/z 229 and 211, also consistent with retention of BME on the hydroxylated vanilloid ring, where m/z 211 was consistent with the loss of H_2O from m/z 229, and m/z 170 and 153 corresponded to the unmodified alkyl fragments derived from capsaicin.²⁰

Identification of a Capsaicin Dimer. Two capsaicin dimers are known to be produced by peroxidases^{25,26} by the coupling of phenoxyl and/or carbon-centered radical intermediates.²⁷ Figure 6 illustrates that a capsaicin dimer was also produced by human liver microsomes and several individual P450 enzymes. The capsaicin dimer eluted at ~ 46.5 min and exhibited an m/z value of 609 with major fragment ions at m/z 440 and 273 (Figure 6). These ions corresponded to the loss of 1 and 2 alkyl chains (-169) from the dimer. The structure of the dimer was confirmed as 5,5'-dicapsaicin by ^1H and 2D-

Figure 7. Proposed metabolic scheme for the formation of major GSH conjugates and 5,5'-dicapsaicin of capsaicinoids by P450 and peroxidase enzymes. Structures with a red label indicate that the product was detected *in vivo* in mouse liver, serum, or urine, as reported in Table 2.

Table 2. Relative Abundance of Capsaicin, GSH Conjugates, 5,5'-Dicapsaicin, and N-Acetylcysteine Conjugates in Mouse Liver and Urine

analyte	% total in liver extract ^a	% total in mouse urine oral (2.5 mg/kg)/I.V. (2.5 mg/kg) doses ^b

^aValues are percentages of total GSH conjugates detected in liver 30 min after i.p. injection with 10 mg/kg capsaicin. N.D. implies that the conjugate was not detected. ^bValues are the percentages of N-acetylcysteine conjugate and capsaicin in urine, determined using the sum of peak area ratios as the denominator and individual peak ratios as the numerator. Five livers were pooled and processed in parallel for control and treated mice. Pooled urine from 24 h (*n* = 5), 48 h (*n* = 2), and 96 h (*n* = 2) oral (2.5 mg/kg) or i.v. (2.5 mg/kg) treatments was used.

gHSQC NMR analysis of the HPLC purified product. The ¹H NMR spectrum demonstrated two aromatic proton resonances at 6.8–6.9 ppm corresponding to the protons at C₂ and C₆ positions that lacked *ortho*-coupling (Supporting Information Figure 1), consistent with a symmetrical dimer formed between C₅ of two capsaicin molecules. Additionally, the 2D gHSQC spectrum showed only two correlations, further indicating a

symmetrical dimer (Figure 6). Finally, acetylation of the dimer using octanoyl chloride confirmed the existence of two free hydroxyl groups on the dimer ring structure. The major product of the reaction was *m/z* 889, which fragmented to yield *m/z* 749, the monoacetylated ion, which further fragmented during MS³ to yield *m/z* 609, 440, and 273 (i.e., the original dimer product) (Supporting Information Figure 2). 5,5'-

Dicapsaicin was produced primarily by CYP2D6, 2C9, and 2C8 but substantially less than that of HRP. Dimer formation was not affected by the addition of GSH, indicating low reactivity of the precursor intermediates. For human liver microsomes, the K_m for dimer formation was $\sim 260 \mu\text{M}$ (Table 1). The dimer was a minor metabolite representing $\sim 0.3\%$ of the total conjugates formed (Table 1).

Assessment of GSH Conjugate Formation *In Vivo*.

Similar to the *in vitro* studies, the O-demethylated conjugate G2 was the most abundant ($\sim 47\%$ total) conjugate detected in livers of capsaicin-treated mice (Table 2). The quinone methide-derived G3 and G6 conjugates were also detected in liver extracts, representing 24% and 23% of the total, respectively. G8 was detected at $\sim 6\%$ of the total, but no other conjugates or the dimer were observed. Similarly, in mouse urine following either oral (2.5 mg/kg) or i.v. (2.5 mg/kg) capsaicin treatment, N-acetylcysteine conjugates corresponding to O-demethylated capsaicin (G2), the quinone methide derived C₇ conjugate (G3), the aromatic quinone methide conjugate (G6), and 5-OH-capsaicin (G8) were detected (Table 2).

DISCUSSION

Understanding the metabolism of capsaicinoids by P450 enzymes is important because humans are widely exposed to capsaicinoids, and metabolism is a major determinant of their pharmacological and toxicological properties. Previous studies on capsaicinoid metabolism have suggested the formation of quinone, phenoxyl radical, and epoxide intermediates.^{27,28} Additionally, P450 metabolism of capsaicin caused genotoxicity,^{27,29} covalent binding of $^3\text{[H]}$ -dihydrocapsaicin to hepatic microsomal proteins *in vivo*, and inhibition of P450 activity, including ethylmorphine deethylation by rat liver microsomes, prolongation of pentobarbital-induced sleep time,²⁸ inhibition of NNK bioactivation *in vitro*,⁶ and inhibition of CYP2E1 *in vitro* by dihydrocapsaicin.³⁰ However, the origins and characteristics of the implied reactive metabolites were not determined.

This study provides new information on the formation of P450-generated reactive metabolites of capsaicin. Specifically, GSH and BME conjugates derived from quinone methide and quinone electrophiles of O-demethylated (M6), C₅ (M5), and C₆ (M7) aromatic hydroxylated and/or oxygenated imide (M8) metabolites of capsaicin, capsaicin itself, as well as the corresponding alkyl dehydrogenated forms of capsaicin (M1 and M4), were characterized. Although structurally similar alkyl phenols are known to form quinone methide intermediates as a result of P450 metabolism,^{31–33} this metabolic process had not previously been demonstrated for capsaicinoids. The formation of a phenoxyl radical intermediate from capsaicin during P450 metabolism has also been proposed but not shown. Studies of peroxidase-mediated capsaicinoid metabolism identified 5,5'-dicapsaicin and 4'-O-5-dicapsaicin ether metabolites.^{25,26} Here, formation of the 5,5'-dicapsaicin dimer by several P450 enzymes and HRP was demonstrated indicating that P450 enzymes are also capable of oxidizing capsaicin to free radical intermediates. Finally, the formation of metabolites via sequential metabolism of capsaicin by P450 enzymes to produce alkyl dehydrogenated and vanilloid ring-modified products (i.e., the G* adducts) was novel. The identification of the G* conjugates, while minor, was interesting as it suggests that, while alkyl dehydrogenation of capsaicin (i.e., M1 and/or M4) diminishes activation of the capsaicin receptor (i.e., TRPV1) and TRPV1-mediated cytotoxicity,^{20,34} these meta-

bolic processes do not inhibit bioactivation of capsaicinoids to potentially toxic electrophiles. Similar conclusions can be made regarding O-demethylation (M6→G1 and G2) and aromatic hydroxylation (M5→G7 and G8 and M7/M8→G9), which either diminish or would be predicted from structure–activity studies to lessen activation of TRPV1^{20,22} but readily form electrophiles.

The majority of GSH and BME conjugates were produced by CYP1A2, 2C19, 2D6, and 3A4 at concentrations likely to occur at sites of exposure and/or absorption and metabolism (e.g., skin, intestine, and liver) (Figure 3 and Supporting Information Figure 10). While there have been reports of capsaicinoid-induced inhibition of CYP enzyme function, most notably CYP2E1,^{28,30,34} the formation of electrophilic intermediates by other CYPs is intriguing since a similar loss of function of CYP1A2, 2C19, 3A4, or 2D6 could have significant consequences that include a loss of or change in the metabolic clearance mechanisms of capsaicinoids and other xenobiotics, potentially leading to unanticipated and undesirable effects. Accordingly, several recent studies indicated that capsaicinoids broadly inhibit CYP enzymes, including CYP1A2, 2C9, 2C19, and 3A4/5, via a competitive mechanism and that CYP3A4, 2B6, and 2D6 are potentially inhibited through a mechanism-based process similar to CYP2E1.^{35,36} Finally, differential formation of G3 versus G6 by CYP3A4 and 2D6, respectively, was observed (Figure 3). Both conjugates appear to originate from a common quinone methide intermediate. However, CYP2D6 produced almost exclusively the C₆ conjugate, G6, versus the more thermodynamically favorable C₇ conjugate G3, as observed with CYP3A4 and other CYP enzymes (Figure 3). These data imply that specific enzyme/substrate interactions play vital roles in the initial bioactivation of the substrates and in determining how GSH interacts with electrophiles during the catalytic process.

The biological significance of reactive intermediate formation from capsaicinoids has not been thoroughly investigated. However, several studies have demonstrated that capsaicinoids may be chemopreventive.^{6–10,37} Capsaicinoids reduce lung tumor formation and growth of transformed foci in animals treated with a mixture of the model carcinogens diethyl-, dibutyl-, and dimethylnitrosamine, and dimethylnitrosourea.³⁸ Efficacy was also shown in models of prostate and pancreatic cancer^{9–12,39,40} as well as in azoxymethane-induced gastric,⁴¹ colon,⁴² and 4-nitroquinoline-1-oxide-induced tongue⁴³ carcinogenesis models. Paradoxically, capsaicinoids were also reported to act as cocarcinogens in other organs in some of the same models,³⁸ and increased rates of liver and stomach cancer have been reported by epidemiological studies of populations that routinely consume high quantities of peppers.³⁷ These results are consistent with previous reports of genotoxicity for capsaicinoids following S9 bioactivation.^{27,29}

Explanations for differences in promotion and/or prevention of cancer cell growth in different tissue and cell types are lacking. One hypothesis is that capsaicinoids attenuate pro-carcinogen bioactivation since capsaicinoids appear to inhibit P450 enzymes (including CYP2E1) involved in ethylmorphine deethylation (CYP2D6 and 3A4),²⁸ pentobarbital clearance (CYP2B6),²⁸ NNK bioactivation (CYP2A6 and 2A13),^{6–8} and benzo[a]pyrene bioactivation (CYP3A4).^{44–46} Alternate hypotheses suggest that capsaicinoids are potent antioxidants, that capsaicinoids preferentially cause cell death in cancer cells that express TRPV1,^{40,47} or selectively inhibit tumor NADH oxidase (tNOX or PMOR).^{9,10} Unfortunately, all of these hypotheses

do not fully address the incongruent effects of capsaicinoids in different tissue types using different tumor models. On the basis of the findings of this study and prior studies of TRPV1-mediated cytotoxicity of capsaicinoids, we posit that the cumulative degree of metabolic destruction, bioactivation, and TRPV1 activation balances the acute cytotoxic and chemopreventive effects versus the cocarcinogenic activity of capsaicinoids in different cell/tissue types. Specifically, cells/tissues with high P450 content, particularly CYP1A2 and 3A4, but low TRPV1 expression (e.g., liver) may be sensitized to carcinogens through additive macromolecule modification by electrophiles. Conversely, cells/tissues with high TRPV1 expression and low P450 expression (e.g., lungs, prostate, and pancreas) may be more susceptible to acute cytotoxicity through TRPV1-mediated signaling. Partially supporting this hypothesis, we have shown that human lung adenocarcinoma (A549) cells express more TRPV1 and are more sensitive to cytotoxicity by capsaicin than human hepatoma (HepG2) cells.^{34,48} Furthermore, inhibition of P450 function in both cell types using 1-aminobenzotriazole increased the cytotoxicity of capsaicin, with HepG2 cells exhibiting a much greater degree of sensitization, consistent with greater detoxification of capsaicinoids by P450 enzymes.^{20,34,48}

In conclusion, capsaicinoids are highly amenable to biotransformation by P450 enzymes and peroxidases. These enzymes produce a variety of products including O-demethylated, oxygenated, dehydrogenated, electrophilic, and free radical metabolites. The biological significance of capsaicinoid bioactivation remains enigmatic; however, the identification of electrophilic metabolites and the elucidation of specific enzymatic and chemical mechanisms of formation will facilitate future studies evaluating capsaicinoids as pharmaceutical and/or cytotoxic and chemopreventive agents.
